Abstract

An “analytic continuation” of a Hermitian matrix representing the conventional fermion-number *operator*, leads to a new, and unconventional, *internal* description of *quarks* and *leptons*. This phenomenological description, unlike the conventional standard-model description, is capable of explaining, among other things, why there are just *three* families of quarks and leptons. These facts provide indirect evidence that the analytic continuation in question somehow reflects physics at the Planck level where flavor degrees-of-freedom presumably originate.

1.0 Introduction and Background

Given the number of flavors of quarks and leptons, and an appropriate (renormalizable) lagrangian, the so-called “accidental symmetries” of the lagrangian [1] are known to “explain” the separate conservation of various (global) “charges” (e.g., lepton number, baryon number, strangeness, charm, truth, beauty, electron-, muon- and tau-numbers). However, there is nothing in such lagrangians, or their associated accidental symmetries, that would

*To be presented at DPF 2000 at The Ohio State University, Columbus, OH, August 9–12, 2000. Download from the APS e-print archive at: <http://publish.aps.org.eprint/>. Paper number: aps2000mar19_003.

explain quarks and leptons, or tell us how many flavors of quarks and leptons to include. What is needed is a “spectrum-generating” mechanism for these particles.

The current “consensus” in particle physics, at least among string theorists, seems to be that fundamental-fermion flavor degrees-of-freedom arise at the Planck level [2, 3]—or possibly at TeV energies in the event that the extra dimensions are “large” [4]—in a theory of superstrings. The purpose of the present paper is to identify an apparently different, but probably complementary, (phenomenological) spectrum-generating mechanism that arises in what seems to be a most unlikely way.

We have found that an “analytic-continuation” [5] of a Hermitian matrix $\mathbf{F}(\text{op})$ representing the conventional fermion-number *operator*, from an *external* spacetime and Hilbert-space setting to a new *internal* (real) non-Euclidean space— $\mathbf{F}(\text{op})$ is continued to a real, generally non-diagonal matrix $\mathbf{F}(v)$ involving a single *real* parameter v —“automatically” leads to a new description of fundamental fermions (quarks and leptons) in which families are *replicated* and there are just *three* families. The fact that this happens, suggests that there is some deep connection between the result of the aforementioned “analytic-continuation,” namely $\mathbf{F}(v)$, and Planck-level physics where flavor degrees-of-freedom, and family-replication, presumably originate.

The work presented here is based on a little-known book by the author [6] wherein many of the consequences of using $\mathbf{F}(v)$ to describe fundamental fermions, are worked out in much greater detail than in the present paper. And, conversely, certain themes that were only alluded to in [6], such as the “analytic-continuation” $\mathbf{F}(\text{op}) \rightarrow \mathbf{F}(v)$, are discussed in much greater detail here. The author hopes that the following relatively brief “overview” and extension of [6] will serve to increase awareness of these new ideas among particle physicists.

2.0 The Conventional Fermion-Number Operator

Consider the situation, presumably at some high energy, where we are dealing with “free” (isolated) leptons or “analytically free” quarks. Suppose we want to describe the scalar fermion-number carried by these particles. And, suppose further that the energies involved are not so high that quantum field-theory (QFT) breaks down. Under these conditions the fermion-number can be represented by a $U(1)$ -type scalar “charge” [7, 8], namely, a charge associated with the (continuous) group of unitary matrices U of order 1 known

as $U(1)$.

The fermion-number operator, which can be represented by a Hermitian matrix $\mathbf{F}(\text{op})$, is said to generate these so-called “gauge” (or phase) transformations, which in turn act on fermion and antifermion quantum states in Hilbert space. That is, given that α is a *real* phase one has

$$U = e^{i\alpha\mathbf{F}(\text{op})}, \quad (1)$$

and for infinitesimal transformations [i.e., $e^{i\delta\alpha\mathbf{F}(\text{op})} = 1 + i\delta\alpha\mathbf{F}(\text{op})$] acting on single-particle (free or “asymptotically free”) fermion and antifermion states $|p\rangle$ and $|\bar{p}\rangle$, respectively, one easily establishes that (the fermion-number “charges” are $f_m = -f_a = 1$ for matter and f_a for antimatter)

$$\begin{aligned} U|p\rangle &= e^{i\delta\alpha f_m}|p\rangle \\ U|\bar{p}\rangle &= e^{i\delta\alpha f_a}|\bar{p}\rangle, \end{aligned} \quad (2)$$

since, by definition, $\mathbf{F}(\text{op})$ obeys the eigenvalue equations

$$\begin{aligned} \mathbf{F}(\text{op})|p\rangle &= f_m|p\rangle \\ \mathbf{F}(\text{op})|\bar{p}\rangle &= f_a|\bar{p}\rangle. \end{aligned} \quad (3)$$

Finally, the assumption that the Hamiltonian H is invariant under U , namely

$$H = UHU^\dagger, \quad (4)$$

ensures that H and $\mathbf{F}(\text{op})$ commute

$$[\mathbf{F}(\text{op}), H] = 0, \quad (5)$$

as can be verified by differentiating $UHU^\dagger$ with respect to α . Hence, the total fermion-number (the number of *fermions* minus the number of *antifermions*) is a constant of the motion.

2.1 Matrix representation of the fermion-number operator

Because the matrix $\mathbf{F}(\text{op})$ involves just *two* kinds of quantum states (3), namely $|p\rangle$ and $|\bar{p}\rangle$, it can be expressed as a 2×2 diagonal Hermitian matrix

(see below), where one of the adjustable parameters (θ) is a *fixed* constant (up to 2π) and the other (ϕ) is freely *adjustable*. In particular,

$$\mathbf{F}(\text{op}) = \left(\begin{array}{cc} \cos \theta & \sin \theta e^{-i\phi} \\ \sin \theta e^{+i\phi} & -\cos \theta \end{array} \right) \Big|_{\cos \theta=1} = \sigma_z, \quad (6)$$

where

$$\sigma_z = \left(\begin{array}{cc} f_m & 0 \\ 0 & f_a \end{array} \right) \quad (7)$$

is one of the familiar Pauli matrices.

This form for $\mathbf{F}(\text{op})$ is consistent with (3) where the normalization and orthogonality conditions, namely $\langle p|p \rangle = \langle \bar{p}|\bar{p} \rangle = 1$ and $\langle p|\bar{p} \rangle = \langle \bar{p}|p \rangle = 0$, respectively, directly yield

$$\mathbf{F}(\text{op}) = \left(\begin{array}{cc} \langle p|\mathbf{F}(\text{op})|p \rangle & \langle p|\mathbf{F}(\text{op})|\bar{p} \rangle \\ \langle \bar{p}|\mathbf{F}(\text{op})|p \rangle & \langle \bar{p}|\mathbf{F}(\text{op})|\bar{p} \rangle \end{array} \right) = \sigma_z. \quad (8)$$

Note that owing to (7) and (8), $\cos \theta < 1$ in (6) is excluded. Here it should also be noted that $\text{tr} \mathbf{F}(\text{op}) = f_m + f_a = 0$, $\det \mathbf{F}(\text{op}) = f_m \cdot f_a = -1$, and $\mathbf{F}^2(\text{op}) = \mathbf{I}_2$ is the 2×2 identity matrix.

3.0 The Continuation From $\mathbf{F}(\text{op})$ to $\mathbf{F}(v)$

Now perform an “analytic continuation” [5] on $\mathbf{F}(\text{op})$, namely $\mathbf{F}(\text{op}) \rightarrow \mathbf{F}(v)$, which maintains $\mathbf{F}(v)$ *real* and $\cos \theta \geq 1$. This can only be accomplished by continuing θ from a *real* to an *imaginary* number, and by maintaining $e^{-i\phi}$ *imaginary*. In particular, to maintain $\mathbf{F}(v)$ real, we must make the replacements $\theta \rightarrow iv$ and $e^{-i\phi} \rightarrow \mp i$, where v is a *real* number. Then

$$\mathbf{F}(v) = \left(\begin{array}{cc} \cos \theta & \sin \theta e^{-i\phi} \\ \sin \theta e^{+i\phi} & -\cos \theta \end{array} \right) \Big|_{\theta=iv, e^{-i\phi}=\mp i} \quad (9)$$

or

$$\mathbf{F}(v) = \left(\begin{array}{cc} \cosh v & \pm \sinh v \\ \mp \sinh v & -\cosh v \end{array} \right), \quad (10)$$

where, just as for $\mathbf{F}(\text{op})$ the eigenvalues of $\mathbf{F}(v)$ are f_m and f_a , and so we have $\text{tr} \mathbf{F}(v) = f_m + f_a = 0$, $\det \mathbf{F}(v) = f_m \cdot f_a = -1$, and $\mathbf{F}^2(v) = \mathbf{I}_2$.

In [6, p. 50 and 54] it is shown that only the upper signs in (10) have physical significance and $v \geq 0$. And, just what is the physical significance of $\mathbf{F}(v)$?

Because the continuation “connects” $\mathbf{F}(\text{op})$ and $\mathbf{F}(v)$, it is natural to assume that both $\mathbf{F}(\text{op})$ and $\mathbf{F}(v)$ describe, or represent, aspects of the fermion number (i.e., the matter-antimatter “degree-of-freedom”). However, unlike $\mathbf{F}(\text{op})$, $\mathbf{F}(v)$ will be shown to describe additional “degrees-of-freedom” such as the “up”-“down” and quark-lepton “degrees-of-freedom.” Moreover, it is abundantly clear from (10) that the generally non-Hermitian (when $v \neq 0$) matrix $\mathbf{F}(v)$ —unlike the Hermitian matrix $\mathbf{F}(\text{op})$ in (8), which acts on Hilbert space—does *not* act on a Hilbert space in an *external* spacetime setting [9].

3.1 A new internal non-Euclidean space

When the matrix $\mathbf{F}(v)$ acts on a real column-vector $\{a, b\}$, it leaves the quadratic form $a^2 - b^2$, invariant. Therefore, the 2-space metric is non-Euclidean or “Lorentzian”, and can be represented by the matrix

$$\mathbf{g} = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}. \quad (11)$$

Given this metric, the *scalar product* of two real vectors assumes the form

$$(a, b)\{e, f\} = ae - bf. \quad (12)$$

Similarly, the *square* of a real vector is given by

$$(a, b)\{a, b\} = a^2 - b^2. \quad (13)$$

Here $(\ , \)$ is a *row* vector while $\{ \ , \ }$ is a (conformable) *column* vector. Now let us demonstrate that these scalar-products transform like *charges* instead of *probabilities* as they would if we were still dealing with a Hilbert space.

3.2 Charge conjugation

The matrix $\mathbf{X}$, where $\mathbf{X} = \mathbf{X}^{-1}$ or $\mathbf{X}^2 = \mathbf{I}_2$, given by

$$\mathbf{X} = \begin{pmatrix} 0 & 1/d \\ d & 0 \end{pmatrix}, \quad (14)$$

transforms $\mathbf{F}(v)$ to its $\mathbf{C}$ -reversed counterpart. In particular, given that the components of $\mathbf{F}(v)$, in diagonal form [i.e., $\mathbf{F}(v)_{\text{diag}} = \sigma_z$], transform like (global) “charges” (f_m and f_a), the general similarity transformation must be such that

$$\mathbf{X} \mathbf{F}(v) \mathbf{X}^{-1} = -\mathbf{F}(v), \quad (15)$$

for *any* real d . However, since $\mathbf{X}$ should convert a real vector $\{a, b\}$ to its *orthogonal* antimatter-counterpart

$$\mathbf{X} \{a, b\} = \{b/d, ad\}, \quad (16)$$

we are forced to require

$$(a, b)\{b/d, ad\} = 0, \quad (17)$$

which means that

$$ab/d - abd = 0, \quad (18)$$

or $d^2 = 1$. Therefore, we have two choices for d , namely, $d = \pm 1$. Which one describes the physics of fundamental fermions?

Clearly, when $d = \pm 1$, the *square* of any vector, namely,

$$(a, b)\{a, b\} = a^2 - b^2, \quad (19)$$

changes signs (is $\mathbf{C}$ -reversing) under $\mathbf{X}$. However, in general, the components of a vector $\{a, b\}$ do not change signs under $\mathbf{X}$, i.e., they are not $\mathbf{C}$ -reversing.

For example, when $d = +1$ in (14), the components of real vectors such as $\{a, b\}$ are *not* $\mathbf{C}$ -reversing charge-like quantities, which means that we cannot represent $\mathbf{C}$ -reversing (Lorentz 4-scalar) charges such as electric-charge, charm, isospin or beauty as *components* of such vectors when $d = +1$. However, when $d = -1$, both the square of $\{a, b\}$ *and* its components a and b change signs (are $\mathbf{C}$ -reversing) under $\mathbf{X}$, and can be used to represent such charges. Therefore, from an experimental standpoint, $d = +1$ is excluded (see Ref. 6, p. 8).

We conclude that the matrix $\mathbf{X}$, which plays the role of charge-conjugation (with respect to these global 2-space charges only) in this non-Euclidean 2-space, is proportional to one of the familiar Pauli matrices, namely,

$$\mathbf{X} = -\sigma_x. \quad (20)$$

The foregoing properties of the non-Euclidean charge-like scalars, leads to the following conjecture:

The global (flavor-defining) charges associated with the aforementioned “accidental” symmetries (see Section 1.0), and the global charges associated with the non-Euclidean 2-space, are (essentially) one and the same charges.

As shown in the next section if this conjecture is true it means, among other things, that simultaneous fundamental-fermion flavor eigenstates can be partially specified using an appropriate (mutually-commuting) combination of these (global) 2-space charges [10, 11].

4.0 Representing Flavor Eigenstates and Flavor Doublets in the 2-Space

The continuation from the 2-D Hilbert space to the 2-D non-Euclidean “charge” space, turns out to mean that individual flavors of fundamental fermions can be partially represented in an unconventional way by geometric objects (in the non-Euclidean 2-space) which *differ* from a quantum state, but *from which the quantum states can be inferred or effectively constructed*. In particular, in the non-Euclidean 2-space, an object we call a “vector triad” represents “up”-“down” type flavor doublets of fundamental fermions—the “up”-“down” type flavor dichotomy. That is, the components of the vectors associated with a given vector-triad are *observable* (Lorentz 4-scalar) “charges,” which can be used to (partially) define the two flavor-eigenstates in a flavor doublet [10, 11].

4.1 Flavor eigenstates

As demonstrated in detail in [6, pp. 16–18], given the charge-like (**C**-reversing) *observables* associated with the description involving $\mathbf{F}(v)$, namely, the real **C**-reversing scalar-components of various matrices and vectors defined on the internal non-Euclidean 2-space, it is possible to write down flavor eigenstates [10, 11].

What one does is to identify the mutually-commuting **C**-reversing “charges” (call them C_i) or charge-like quantum numbers associated with a particular flavor, and then write the corresponding simultaneous flavor-eigenstate as

$$|C_1, C_2, C_3, \dots, C_n\rangle. \quad (21)$$

Here $C_1, C_2, C_3, \dots, C_n$, are the “good” charge-like quantum numbers (charges) associated with a particular flavor. It happens that these *observable* real-numbers can be identified with quantum numbers such as *electric charge*, *strangeness*, *charm*, the third-component of (global) *isospin*, *truth and beauty* (See Ref. 6, p. 72). To discover what charges describe a particular flavor we must first identify the vector-triad associated with that flavor.

Now, each *vector-triad* represents a flavor doublet, not just an individual flavor. That is, vector-triads provide information on *two* quantum states (simultaneous flavor-eigenstates) associated with flavor doublets. Therefore, vector-triads represent both individual flavors *and* flavor doublets. Here we simply summarize how it is that non-Euclidean vector-triads represent both *individual* flavors and “up”-“down” type *flavor-doublets*.

4.2 Flavor doublets

Consider the eigenvector (call it $\mathbf{Q}$) of $\mathbf{F}(v)$ for fundamental fermions [12]. Since the space on which $\mathbf{F}(v)$ “acts” is two-dimensional, the *observable* vector $\mathbf{Q}$ can be “resolved” into two (no more or less) *observable*, linearly-independent vectors, call them $\mathbf{U}$ and $\mathbf{V}$, as $\mathbf{Q} = \mathbf{U} + \mathbf{V}$ [13]. Now, because these three vectors ($\mathbf{Q}$, $\mathbf{U}$, and $\mathbf{V}$) are *simultaneous* observables, it makes sense to speak of this “triad” of vectors as being a well defined geometric object, namely, a “vector triad.”

Recognizing that the components of $\mathbf{Q}$, $\mathbf{U}$ and $\mathbf{V}$ are $\mathbf{C}$ -reversing charge-like *observables* we can write these *observable* “charge” vectors as

$$\mathbf{Q} = \{q_1, q_2\} \quad (22)$$

$$\mathbf{U} = \{u_1, u_2\} \quad (23)$$

$$\mathbf{V} = \{v_1, v_2\}, \quad (24)$$

where q_1, q_2, u_1, u_2, v_1 and v_2 are the various *observable* “charges” (e.g., q_1 and q_2 are found to be *electric* charges). Given $\mathbf{Q} = \mathbf{U} + \mathbf{V}$, the non-Euclidean metric (11), and Eqs. (22) through (24), we find the associated *observable* quadratic-“charges”

$$\mathbf{Q}^2 = \mathbf{U}^2 + 2\mathbf{U} \bullet \mathbf{V} + \mathbf{V}^2 \quad (25)$$

$$2\mathbf{U} \bullet \mathbf{V} = 2(u_1 v_1 - u_2 v_2) \quad (26)$$

$$\mathbf{U}^2 = u_1^2 - u_2^2 \quad (27)$$

$$\mathbf{V}^2 = v_1^2 - v_2^2. \quad (28)$$

Finally, using the foregoing charges, we can express the *two* quantum states (simultaneous flavor-eigenstates) associated with a *single* vector-triad in the form of “ket” vectors as follows (Ref. 6, pp. 16–18)

$$\begin{aligned} &|q_1, u_1, v_1, \mathbf{Q}^2, \mathbf{U}^2, 2\mathbf{U} \bullet \mathbf{V}, \mathbf{V}^2\rangle, \\ &|q_2, u_2, v_2, \mathbf{Q}^2, \mathbf{U}^2, 2\mathbf{U} \bullet \mathbf{V}, \mathbf{V}^2\rangle. \end{aligned} \quad (29)$$

Here, the state $|q_1, u_1, v_1, \mathbf{Q}^2, \mathbf{U}^2, 2\mathbf{U} \bullet \mathbf{V}, \mathbf{V}^2\rangle$ represents the “up”-type flavor-eigenstate, and $|q_2, u_2, v_2, \mathbf{Q}^2, \mathbf{U}^2, 2\mathbf{U} \bullet \mathbf{V}, \mathbf{V}^2\rangle$ represents the corresponding “down”- type flavor-eigenstate in a flavor doublet of fundamental fermions [10, 11].

Up to this point in the discussion we have shown that the 2-space description naturally incorporates the matter-antimatter dichotomy and the “up”-“down” flavor dichotomy. Now let us demonstrate how quarks and leptons are incorporated in the new description.

4.3 Distinguishing quarks and leptons

Choosing the upper signs in (10), the matrix $\mathbf{F}(v)$ becomes

$$\mathbf{F}(v) = \begin{pmatrix} \cosh v & \sinh v \\ -\sinh v & -\cosh v \end{pmatrix}, \quad (30)$$

where v is a positive real number [6, p. 50 and 54].

As described in [6, pp. 52–55], the parameter v distinguishes between *quarks* and *leptons*. In particular, the parameter v is found to be *quantized* and obeys the “quantum condition”:

$$v = \ln M_c, \quad (31)$$

where M_c counts both the *number* of fundamental fermions in a strongly-bound composite fermion, and the *strong-color multiplicity*. That is, $M_c = 3$ for quarks (strong-color triplets) and $M_c = 1$ for leptons (strong-color singlets).

4.3.1 Quark and lepton electric charges

It is shown in (Ref. 6, pp. 52–55, and Ref. 12) that the quark and lepton electric charges are the “up”-“down” components of the eigenvectors of the

matrix $\mathbf{F}(v)$. In particular, the quark charges are given by ($M_c = 3$)

$$q_1(f) = \frac{(M_c^2 - 1)}{2M_c(M_c - f)} = +\frac{2}{3} \text{ for } f = +1 \text{ and } +\frac{1}{3} \text{ for } f = -1 \quad (32)$$

$$q_2(f) = q_1(f) - 1. \quad (33)$$

Similarly, the lepton electric charges are given by ($M_c = 1$)

$$q'_1(f) = \frac{-(M_c^2 - 1)}{2M_c(M_c - f)} = -1 \text{ for } f = +1 \text{ and } 0 \text{ for } f = -1 \quad (34)$$

$$q'_2(f) = q'_1(f) + 1. \quad (35)$$

In summary, $\mathbf{F}(v)$ is found to provide an explanation for the quark-lepton “dichotomy” of fundamental fermions in addition to the matter-antimatter, and “up”-“down” type flavor-dichotomy.

4.4 Family replication and the number of families

In [6, pp. 59–65] it is shown that flavor doublets (hence families) are *replicated* and that there are only three families of quarks and leptons. We refer the reader to [6] for a full and detailed account. Here we simply outline how this situation comes about.

By the definition of a linear-vector 2-space, a 2-vector such as $\mathbf{Q}$ can always be resolved into a pair (no more, or less) of linearly-independent vectors $\mathbf{U}$ and $\mathbf{V}$ as $\mathbf{Q} = \mathbf{U} + \mathbf{V}$ (see Sec. 4.2). And, since $\mathbf{Q}$ *represents* a flavor doublet, so should $\mathbf{U}$ and $\mathbf{V}$ *represent* this *same* flavor doublet. But, if this is so, *different vector-resolutions of $\mathbf{Q}$ (i.e., different vector-triads) should correspond to different flavor-doublets having the same $\mathbf{Q}$.* In other words, flavor doublets should be *replicated*.

Since $\mathbf{Q}$ can be resolved (mathematically) in an infinite number of ways, we might suppose that there are an *infinite* number of flavor doublets, and hence, families. But, because of various “quantum constraints,” it is possible to show that $\mathbf{Q}$ *can be resolved in only three physically acceptable ways for $\mathbf{Q}$ -vectors associated with either quarks or leptons.* In other words, there can be only six quark flavors and six lepton flavors, which leads to the (*ex post facto*) “prediction” of three quark-lepton families.

5.0 Discussion

It is important to understand that the new 2-space description of fundamental fermions (quarks and leptons) provides a distinction between these particles that goes beyond differences that can be explained by mass differences alone. For example, in the standard model the only difference between an electron and a muon is that they have different masses. Otherwise, these particles experience identical electroweak interactions. Moreover, as described in Section 1.0, the separate conservation of electron- and muon-numbers can be attributed to certain unavoidable “accidental symmetries” associated with the (renormalizable) lagrangian describing the (electroweak) interactions of these particles.

Taken at face value, these accidental symmetries would seem to imply that there are no internal “wheels and gears” that would distinguish an electron from a muon, for example. But, if the string theories are correct, these particles would be associated with different “handles” on the compactified space [see Ref. 3, Vol. 2, p. 408], and so would be different in this *additional* sense. Likewise, in the present non-Euclidean 2-space description, a variety of (global) 2-scalars, which are only *indirectly* related to the accidental symmetries of the lagrangian, serve to provide a (further) distinction between particles such as the electron and muon (see also the conjecture in Sec. 3.2).

A probable experimental signal of such “internal” differences is to be found in the recent observations at the Super Kamiokande of bi-maximal neutrino mixing [14]. Models which begin by positing a neutrino mass-matrix and associated mixing-parameters, such as the three-generation model proposed by Georgi and Glashow [15], do a good job of describing the observations. However, bi-maximal mixing may have a deeper explanation in terms of internal topological-differences (in the non-Euclidean 2-space) between ν_e , and ν_μ or ν_τ neutrinos.

With respect to the internal transformation $\mathbf{F}(v)$, the topology of the non-Euclidean “vector triad” (see Sec. 4.2) representing the ν_e (ν_μ or ν_τ), is found to be that of a cylinder (Möbius strip). And, assuming that a change in topology during neutrino mixing is suppressed by energy “barriers,” or other topological “barriers” (e.g., one cannot continuously deform a doughnut into a sphere), while neutrino mixing without topology-change is (relatively) enhanced, one can readily explain the experimental observation of (nearly) maximal $\nu_\mu - \nu_\tau$ neutrino mixing—at least maximal $\nu_\mu - \nu_\tau$ mixing over long distances, where the foregoing topological influences would

be cumulative [16]. If this explanation is basically correct, then it follows that the neutrino mass-matrix and associated mixing-parameters needed to explain bi-maximal neutrino mixing, would be the *result*, at least in part, of these deeper (internal) topological differences between neutrinos, and not their *cause*.

6.0 Conclusions

It is widely believed that the explanation for fundamental-fermion (quark and lepton) family replication is to be found in theories of quantum gravity (e.g., superstrings). And, yet, as demonstrated here and elsewhere [6], a simple “analytic continuation” of a Hermitian matrix representing the fermion-number operator, leads to a new, and unconventional, *internal* description of *quarks* and *leptons*, which also explains family replication. In particular, this description, unlike the conventional standard-model description, is capable of explaining, among other things, the fact that there are just *three* observed families of quarks and leptons. We take these facts to be evidence that the (phenomenological) “analytic continuation” $\mathbf{F}(\text{op}) \rightarrow \mathbf{F}(v)$, or at least the result of the continuation $\mathbf{F}(v)$, somehow reflects physics at the Planck level where flavor degrees-of-freedom presumably originate.

It seems that the best chance to show that $\mathbf{F}(v)$ and Planck-level physics are related, lies in an appropriate application of superstring theory. Accordingly, the author hopes that the new description of families presented here (see also Refs. 6 and 16) will encourage string theorists working on so-called realistic (free-fermionic) three-generation string models (e.g., see Refs. 17, 18), to take up the challenge of showing that these models either do, or do not, justify the new description.

The term “analytic continuation” usually refers to an individual analytic function. However, we are dealing here with the “analytic continuation” of a 2 by 2 *matrix* $\mathbf{F}(\text{op})$ whose components are four different, but closely related, analytic functions ($\pm \cos \theta, \sin \theta e^{\pm i\phi}$). Because the term “analytic continuation” has a precise mathematical meaning, and because we would prefer to avoid confusion with well-established mathematical terminology, we will relax this precision in favor of the term “continuation” (without quotes) or “analytic continuation” (with quotes) whenever we refer to the continuation or “analytic continuation” of the matrix $\mathbf{F}(\text{op})$.

Additional information: <http://physicsweb.org/TIPTOP/> or <http://www.amazon.com/exec/obidos/ISBN=0965569500>. In spite of the many successes of the standard model of particle physics, the observed proliferation of matter-fields, in the form of “replicated” generations or families, is a major unsolved problem. In this book I propose a new organizing principle for fundamental fermions, i.e., a minimalistic “extension” of the standard model based, in part, on the Cayley-Hamilton theorem for matrices. In particular, to introduce (internal) global degrees of freedom that are capable of distinguishing all observed flavors, I use the Cayley-Hamilton theorem to generalize the familiar standard-model concept of scalar fermion-numbers f (i.e., $f_m = +1$ for all fermions and $f_a = -1$ for all antifermions). This theorem states that *every (square) matrix satisfies its characteristic equation*. Hence, if f_m and f_a are taken to be the eigenvalues of some real matrix $\mathbf{F}(v)$ —a “generalized fermion number”—it follows from this theorem that both f and $\mathbf{F}(v)$ are square-roots of unity. Assuming further that the components of both $\mathbf{F}(v)$ and its eigenvectors are global charge-like quantum observables, and that $\mathbf{F}(v)$ “acts” on a (real) vector 2-space, both the form of $\mathbf{F}(v)$ and the 2-space metric are determined. I find that the 2-space has a non-Euclidean or “Lorentzian” metric, and that various associated 2-scalars serve as global flavor-defining “charges,” which can be identified with charges such as strangeness, charm, baryon and lepton numbers etc.. Hence, these global charges can be used to describe individual flavors (i.e., flavor eigenstates), flavor doublets and families. Moreover, because of the aforementioned non-

Euclidean constraints, and certain standard-model constraints, I find that these global charges are effectively- “quantized” in such a way that families are replicated. Finally, because these same constraints dictate that there are only a limited number of values these charges can assume, I find that families always come in “threes.”

[9] Even though $\mathbf{F}(v)_{\text{diag}} = \mathbf{F}(\text{op}) = \sigma_z$, these two matrices act on entirely different spaces, since $\mathbf{F}(\text{op})$ is associated with the *constant* $\cos \theta = 1$, and the *variable* phase-factor $e^{-i\phi}$, whereas $\mathbf{F}(v)$ is associated with the *variable* $\cos \theta \geq 1$, and the *constant* phase-factor $e^{+i\phi} = +i$.

[10] When weak interactions are “turned off” flavor eigenstates and mass eigenstates are one and the same. For the most part, when we speak here of flavor eigenstates, we are referring to the situation where flavor- and mass-eigenstates are the same.

[11] Strictly speaking, besides the specification of global charges, the overall quantum state of a fundamental fermion would, necessarily, involve a specification of the spin state, the energy-momentum state and so on, together with a specification of the particular mix of local color (gauge)-charges R , W , B , G and Y carried by each fundamental fermion. This color-mix would be determined, in turn, by a complementary, local $SU(5)$ color-dependent gauge description.

[12] Any acceptable 2×2 matrix $\mathbf{F}(v)$ possesses just *two*, *real* linearly-independent eigenvectors, call them $\mathbf{Q}$ and $\mathbf{Q}^c$, corresponding to the two *real* eigenvalues f_m and f_a , respectively. Therefore, the matrix $\mathbf{F}(v)$ can be thought of as “producing” the conventional single-particle fermion numbers f_m and f_a via the 2-space eigenvalue equations

$$\mathbf{F}(v)\mathbf{Q} = f_m\mathbf{Q}$$

and

$$\mathbf{F}(v)\mathbf{Q}^c = f_a\mathbf{Q}^c,$$

respectively.

The 2-vector $\mathbf{Q}$ (and its scalar components—the *electric* charges of quarks and leptons) describes *matter*, while the linearly-independent 2-vector $\mathbf{Q}^c$

describes its antimatter counterpart. The superscript c on $\mathbf{Q}^c$ is merely a label signifying antimatter. It is not an exponent or a symbol for complex conjugation. As such, it signifies only that *the 2-vectors $\mathbf{Q}$ and $\mathbf{Q}^c$ are real vectors associated with (“carried by,” “representing,” etc.) individual fundamental-fermions or antifermions, respectively*, not state vectors in some Hilbert space.

Even though the 2-vector $\mathbf{Q}$ ($\mathbf{Q}^c$) does not represent a quantum state, it is associated with the phase factor $e^{i\alpha f_m}$ ($e^{i\alpha f_a}$) associated with a quantum state describing matter (antimatter). To see this, replace $\mathbf{F}(\text{op})$ in Eq. 1 in the main text by $\mathbf{F}(v)$. Then U is replaced by U' where

$$U'\mathbf{Q} = e^{i\alpha f_m}\mathbf{Q}$$

and

$$U'\mathbf{Q}^c = e^{i\alpha f_a}\mathbf{Q}^c.$$

Note that because $e^{in(\delta\alpha)\mathbf{F}(v)} = e^{i\alpha\mathbf{F}(v)}$ when n is very large and $\delta\alpha$ is very small, but nonzero (i.e., $n\delta\alpha = \alpha$), α can be any *finite* number ranging from zero to infinity. Similar arguments apply to the matrix U since $U(\alpha) \cdot U(\alpha') = U(\alpha + \alpha')$.

[13] When we say that the vectors $\mathbf{Q}$, $\mathbf{U}$ and $\mathbf{V}$ are *observables*, we mean that their associated component-“charges” are mutually-commuting simultaneous observables. Hence, all of these charge-like components can be known in principle, at the *same* time, meaning that the vectors $\mathbf{Q}$, $\mathbf{U}$ and $\mathbf{V}$ can be known simultaneously.
